1 Abstract

2 Introduction

3 Methods

3.1 Field

Growth and host plant inoculation seven tropical tree species was conducted at the greenhouses in the Gamboa Research Station, Smithsonian Tropical Research institute, Republic of Panama. The species, *Theobroma cacao*, *Dypterix* sp., *Lacmellea panamensis*, *Apeiba membranacea*, *Heisteria concinna*, *Chrysophyllum caimito*, and *Cordia alliodora* were chosen due to their variance in leaf traits (J.Wright unpublished data) and the availability of seeds in January- April 2019. Seeds of tree species were collected from the forest floor and grown in the greenhouse. Seedlings were kept in a chamber made out of PVC and clear plastic to prevent inoculation from spore fall inside the greenhouse. NEEDS

16 INFORMATION ON THE SOIL MIXTURE AND AUTOCLAVING PROTOCOL. Seedlings reached
17 a minimum of 4 true leaves before endophyte inoculation. Then 10 individual plants of each species
18 were exposed to 10 nights of spore fall to achieve a high endophyte load (E+) and 10 homologous plants
19 were kept inside the greenhouse plastic chamber to maintain a low endophyte load (E-) (Fig. ? MAKE A
20 DIRAGRAM?). Plants exposed to spore fall were placed near (~10 m) the forest edge at dusk (~18:00
21 hours) and returned to the greenhouse at dawn (~07:00 hours) (Bittleston et al. 2011).

22 3.1.1 Leaf trait measurements

23 Three mature leaves were haphazardly collected from each of the individual plants in each treatment
24 (E+, E-) within 7-10 days after inoculation treatment. Anthocyanin (ACI) content and leaf thickness
25 (LT) were measured while the leaf was still attached to the plant. We measured anthocyanin content with
26 ACM-200plus (Opti-Sciences Inc. Hudson, New Hampshire, U.S.A.) on three haphazardly selected lo-
27 cations (working from the petiole out to the leaf tip) on the leaf surface of three haphazardly selected
28 leaves for a total of nine measurements per plant (Tellez et al., 2022). The ACM-200 calculates an
29 anthocyanin content index (ACI) value from the ratio of % transmittance at 931 nm/% transmittance
30 at 525 nm (**opti-sciencesinc?**) . On compound leaves (i.e., *Dypterix* sp.) we measured at three differ-
31 ent leaflets. Leaf thickness (μm) was measured with a Mitutoyo 7327 Micrometer Gauge (Mitutoyo,
32 Takatsu-ku, Kawasaki, Japan) in sthe same manner as the anthocyanin measurements, taking care to
33 avoid major and secondary veins. After anthocyanin and leaf thickness measurements were completed,
34 we removed the leaves from their stems, placed them inside a plastic bag (i.e. Ziploc), place in an ice
35 chest and moved them to the lab for further measurements. Leaf punch strength (LPS) was measured

with an Imada DST-11a digital force gauge (Imada Inc., Northbrook, IL, United States) by conducting punch-and-die tests with a sharp-edged cylindrical steel punch (2.0 mm diameter) and a steel die with a sharp-edged aperture of small clearance (0.05 mm). The leaf punch measurements were taken by puncturing the leaf lamina at the base, mid-leaf and tip on both sides of the mid-vein, avoiding minor leaf veins when possible (Tellez et al., 2022). Once leaf toughness was measured, we used a 7 mm diameter punch hole to puncture disks for leaf mass per area (LMA) measurements. We collected one three disks per leaf (see Supplementary material for details). The disk punches dried at 60 °C for 48-72 hours. before being weighed.

3.1.2 Leaf tissue preparation for molecular work

The selected leaves were also used to profile endophyte community composition, abundance, and richness via amplicon sequencing (Illumina MiSeq). The leaf tissue remaining after the leaf trait measurements had the main vein and margins excised so that only the lamina remained. The lamina was haphazardly cut into 2 x 2 mm segments, enough to obtain a total of 16, and surface sterilized by sequential rinsing in 95% ethanol (10 s), 0.5 NaOCl (2 mins) and 70% ethanol (2 mins), as per (Arnold et al., 2003; Higgins et al., 2014; Tellez et al., 2022). After, leaves were air-dried briefly under sterile conditions. Sixteen leaf segments per leaf, a total of forty-eight leaf segments per plant, were plated in 2% malt extract agar (MEA), sealed with Parafilm M (Bemis Company Inc., U.S.A.) and incubated at room temperature. The cultured leaf segments were used to estimate endophyte colonization of E+ and E- leaves. The presence or absence of endophytic fungi in the leaf cuttings was assessed 7 days after plating. The remaining sterilized leaf lamina was preserved in sterile 15 mL tubes with ~ 10 mL

CTAB solution (1 M Tris-HCl pH 8, 5 M NaCl, 0.5 M EDTA, and 20 g CTAB). Leaf tissue in CTAB solution was used for amplicon sequencing (described in detail below). All leaf tissue handling was performed in a biosafety cabinet with all surfaces sterilized by exposure to UV light for 30 minutes and cleaned sequentially in between samples with 95% ethanol, 0.5% NaOCl and 70% ethanol to prevent cross contamination.

3.2 Amplicon sequencing

Leaf tissue in CTAB solution was stored for 2 months at room temperature prior to being placed at -80 C for 3 months before extracting DNA. In preparation for DNA extraction, we decontaminated all instruments, materials, and surfaces with DNABay (Molecular BioProducts Inc., San Diego, CA, United States), 95% Ethanol, 0.5 % NaOCl, and 70 % Ethanol, and subsequently treated with UV light for 30 minutes in biosafety cabinet. We then transferred 0.2 – 0.3 g of leaf tissue into duplicate sterile 2mL tubes, resulting in 2 subsamples. Total genomic DNA from subsamples was extracted as described in U'Ren & Arnold (2017). In brief, we added two sterile 3.2 mm stainless steel beads to each tube and proceeded to lyophilize samples for 72 hours to fully remove CTAB content from tissue. After this period, we submerged the sample tubes in liquid nitrogen for 30s and proceeded to homogenize samples to a fine powder for 45 s in FastPrep-24 Tissue and Cell Homogenizer (MP Biomedicals, Solon, OH, USA). Afterwards, we repeated the decontamination procedure described before and used QIAGEN DNeasy 96 PowerPlant Pro-HTP Kit (U'Ren & Arnold, 2017) (QIAGEN, Valencia, CA, USA). After all genomic DNA was extracted, we pooled the subsamples for each individual sample before amplification. We used sterile equipment and pipettes with aerosol-resistant tips with filters in all steps before

76 amplification. We followed a two-step amplification approach previously described by Sarmiento et
77 al. (2017) and U'Ren & Arnold (2017). We used primers for the fungal ITSrDNA region, ITS1f (5'-
78 CTTGGTCATTTAGAGGAAGTAA-3') and ITS4 (5'-TCCTCCGCTTATTGATATGC-3') with modi-
79 fied universal consensus sequences CS1 and CS2 and 0–5 bp for phase-shifting. Every sample was
80 amplified in two parallel reactions containing 1–2 µL of DNA template (U'Ren & Arnold, 2017; see
81 also Tellez et al., 2022). We visualized PCR (PCR1) reactions with SYBR Green 1 (Invitrogen, Carls-
82 bad, CA, USA) on 2% agarose gel (Oita et al., 2021). Based on the electrophoresis band intensity, we
83 combined parallel PCR1 reactions and diluted 5 µL of amplicon product with molecular grade water
84 to standardize to a concentration of 1:15 (Sarmiento et al., 2017 for details; Tellez et al., 2022). We in-
85 cluded DNA extraction blanks and PCR1 negatives in this step. We used a separate set of sterile pipettes,
86 tips, and equipment to reduce contamination. We used a designated PCR area to restrict contact with
87 pre-PCR materials (Oita et al., 2021).

88 We used 1 µL of PCR1 product from samples and negative control for a second PCR (PCR2) with
89 barcode adapters (IBEST Genomics Resource Core, Moscow, ID, USA). Each PCR2 reaction (total
90 15 µL) contained 1X Phusion Flash High Fidelity PCR Master Mix, 0.075 µM of barcoded primers
91 (forward and reverse pooled at a concentration of 2 µM) and 0.24mg/mL of BSA following Sarmiento
92 (2017) and U'Ren & Arnold (2017). Before final pooling for sequencing, we purified the amplicons
93 using Agencourt AMPure XP Beads (Beckman Coulter Inc, Brea, CA USA) to a ratio of 1:1 following
94 the manufacturer's instructions. The products were evaluated with Bio Analyzer 2100 (Agilent Tech-
95 nologies, Santa Clara, CA, USA) (Tellez et al., 2022). We quantified the samples through University
96 of Arizona Genetics Core, and subsequently diluted them to the same concentration to prevent over

97 representation of samples with higher concentration, see (CITATION). Amplicons were normalized
98 to 1 ng/μL, then pooled 2 μL of each for sequencing. No contamination was detected visually or by
99 fluorometric analysis. To provide robust controls we combined 5 μL of each PCR1 negative and the
100 DNA extraction blanks and sequenced them as samples. Ultimately, we combined samples into a single
101 tube with 20 ng/μL of amplified DNA with barcoded adapters for sequencing on the Illumina MiSeq
102 platform with Reagent Kit v3 (2 × 300 bp) following protocols from the IBEST Genomics Resource
103 Core at the University of Idaho, USA. Again, we included the DNA extraction blanks and two PCR1
104 negatives and sequenced with samples. Sequencing yielded 3,778,081 total ITS1 reads.

105 **3.2.1 Mock Communities**

106 We processed and sequenced 12 mock communities following the methods described above. This al-
107 lowed us to assess the quality of our NGS data set. We used two mock communities that consisted of
108 PCR product from DNA extractions of 32 phylogenetically distinct fungi, representing lineages that
109 are typically observed as endophytes: Ascomycota, Basidiomycota, Zygomycota and Chytridiomycota
110 (Oita et al., 2021; see Daru et al., 2019 for details). In brief, we used six mock communities with
111 equimolar concentrations of DNA from all 32 fungal taxa and another six mock communities with
112 tiered concentrations of DNA from the same fungal taxa (Daru et al., 2019). Each mock community
113 was sequenced five times (i.e., five replicates) (Oita et al., 2021). The read abundance from the equimo-
114 lar and tiered communities was positively associated with the expected read number (with replicates as
115 a random factor: $R^2_{Adj} = 0.87$, $P = XXXX$, see Supplementary Material). Using mock communities
116 allowed us to evaluate the sequencing effectiveness in communities with known composition and struc-

ture (Bowman & Arnold, 2021). Henceforth, we used read abundance as a relevant proxy for biological OTU abundance (U'Ren et al., 2019).

3.2.2 Bioinformatic analyses

We used VSEARCH (v2.14.1) for *de novo* chimera detection, dereplication and sequence alignment. VSEARCH is an open-source alternative to USEARCH that uses an optimal global aligner (full dynamic programming Needleman-Wunsch), resulting in more accurate alignments and sensitivity (Rognes et al., 2016). For mock communities and experimental samples, we used forward reads (ITS1) for downstream bioinformatics analyses due to their high quality, rather than reverse reads (ITS4). Following Sarmiento et al. (2017), we concatenated all reads in a single file and used FastQC reports to assess Phred scores above 30 and determine the adequate length of truncation. We processed 892,713 of sequence reads from mock communities and 3,778,081 from experimental samples. We truncated mock community and experimental sample reads to a length of 250 bp with command `fast_truncLen` and filtered them at a maximum expected error of 1.0 with command `fast_maxee`. We then clustered unique sequence zero radius OTUs (that is, zOTUs; analogous to amplicon sequence variants (Callahan et al., 2016)), by using commands `derep_fulllength` and `minseqlength` set at 2. Sequentially we denoised and removed chimeras from read sequences with commands `cluster_unoise`, and `uchime3_denovo`, respectively (see Supplementary YYY for details). Finally, we clustered zOTUs at a 95% sequence similarity with command `usearch_global` and option `id` set at 0.95. After which, 3,035,960 sequence reads from experimental samples remained.

Taxonomy was assigned with the Tree-Based Alignment Selector Toolkit [v2.2; Carbone et al. (2019)]

137 by placing unknowns within the Pezizomycotina v2 reference tree (Carbone et al., 2017). ITS sequences
138 were blasted against the UNITE database by the ribosomal database project (RDP) classifier. A total of
139 2147 OTUs hits were obtained and are composed of 68.6% Ascomycota, 26.8% Basidiomycota, <0.05%
140 Chytridiomycota, <0.05% Glomeromycota, <0.05% Mortierellomycota, <0.05% Rozellomycota, 0.05%
141 Kickxellomycota, and 4.2 % BLAST hit misses. Only OTUs representing Ascomycota were used for
142 downstream statistical analyses since foliar endophyte communities in tropical trees are dominated by
143 Ascomycota (Arnold & Lutzoni, 2007).

144 For each OTU identified, we removed laboratory contaminants from experimental samples by subtract-
145 ing the average read count found in control samples from the DNA extraction and PCR steps. Our anal-
146 ysis of mock communities allowed use to identify and remove false OTUs from experimental samples,
147 those with fewer than 10 reads, and remove 0.1% of the read relative abundance across all samples (Oita
148 et al., 2021). Removed reads represent the frequency of reads classified as contamination in the mock
149 communities relative to the expected read count. Three experimental samples from *Theobroma cacao*
150 ($n=2$) and *Apeiba membranacea* ($n=1$) were removed from all analyses due to incomplete entries. Af-
151 ter pruning taxa with zero reads from experimental samples, we identified 260 OTUs found exclusively
152 in control ($E-$) plants ($n=78$) and deemed them as artifacts resulting from the greenhouse conditions.
153 Consequently, these were consistently eliminated from treatment ($E+$) plants across all species. We
154 converted reads for each fungal OTU to proportions of total sequence abundance per sample to reduce
155 differences in sampling effort, following previous studies (Weiss et al. (2017); McMurdie & Holmes
156 (2014)). We then removed singletons and obtained an average of 2,464,558 sequence reads in 529
157 Ascomycota OTUs across 156 experimental samples of 7 tree species. All analyses post taxonomic as-

158 signment were performed in R [v. 4.3.2; R Core Team (2023)] using the phyloseq package (McMurdie
159 & Holmes, 2013) and custom scripts (see Supplementary Material).

160 **3.2.3 Ant-endophyte interaction assays**

161 A fresh fourth leaf was used in ant assays. To assess leaf-cutter ant damage, we introduced one detached
162 leaf per plant per treatment to an actively foraging leaf-cutter ant colony for a two-hour assay. We
163 presented leaf-cutter ant colonies with a choice of an E+ or an E- leaf on one disposable plastic plate
164 next to an active nest trail. Carefully, we collected and placed debris from the trail leading up to the plate
165 to lure ants into the plate. We initiated the ant assay as soon as one ant entered the plate and explored
166 the leaf contents (for ~ 10-20 seconds). Every five minutes we took a digital photo of the choice arena
167 until about 75% of the leaf content of one of the leaves was consumed. We used the digital photo at
168 time zero and at the end of trial to quantify the leaf area removed using ImageJ [v1.52r; Schneider et
169 al. (2012)]. Ant recruitment was estimated by counting individuals in the choice arena throughout trial
170 event.

171 **3.2.4 Pathogen assays**

172 For the pathogen assays, we introduced an agar plug inoculated with hyphae of *Calonectria* sp. ($P+$
173 treatment), and an agar plug without the pathogen ($P-$ control) to similarly aged/sized leaves within 10-
174 14 days after endophyte inoculations (CITATION). Leaves with the $P+$ or $P-$ treatment were misted
175 with sterile water two times a day (morning and afternoon) to maintain moisture. After four days, we

176 removed the plugs and took digital photos to analyze leaf area damage using ImageJ [v1.52r; Schneider
177 et al. (2012)].

178 **3.2.5 Statistical Analyses**

179 We explored how leaf functional traits and foliar fungal symbionts correlated to herbivory and pathogen
180 damage on leaves. We present the analyses at the leaf and at the plant level. Leaf functional traits were
181 measured and are presented in their raw form, at the leaf level, while FEF data was explored and is
182 presented at the plant level. In analyses where leaf functional traits and FEF are combined we used
183 averages of the leaf functional traits.

184 To test for H2, we used a general linear mixed model (GLM) with XXXX as the response variable.
185 To determine which fixed effects to include in the models we used the `vif` function in *R* to calculate
186 the variance inflation factor for all explanatory variables (ACI, LT, LPS and LMA) (R Core Team,
187 2023). We then created a correlation matrix with `cor` function to assess correlations among covariates.
188 We opted to maintain explanatory variables pertaining to physical barriers (LT, LPS and LMA) and
189 exclude ACI from subsequent linear models due to high collinearity with LPS (0.54) and LMA (0.73).
190 Every variable kept exhibits some degree of collinearity and this is well recorded in the literature (CITE
191 HERE).

192 Additionally, Principal Component Analysis (PCA) was used to reduce dimensions among covariates
193 and reveal underlying interactions that could influence fungal endophyte abundance, diversity and com-
194 munity composition in seedlings. The PCA was computed using the `prcomp` function in *R* statistical
195 software (R Core Team, 2023). A complete PCA was computed with variables ACI, LT, LPS, and LMA

196 (FIGURE 2a?). We then proceeded to compute a PCA with the data from leaves of plants used in the
197 ant ($n = 210$) and pathogen assays ($n = 192$).

198 The PCA revealed how covariates (LMA, ACI, Thickness and Toughness) interact. I overlapped tree
199 species groups on the PCA axes to show how the variance in the data is explained by PC1 (60%) and
200 PC2 (27%) (Fig. 4). This is indicative of correlation among covariates. Thickness and toughness were
201 orthogonal to each other in PCA, indicative of low correlation.
